Abstract

Biodentine is bioactive endodontic cement. This case series report contains some common clinical indications where Biodentine been used successfully and some off-label usage of this material, which has enabled successful clinical outcomes. Cases present in the report are from the year 2016 to the present date.

Keywords

Apexification; Bioactive Endodontic Cement; Biodentine; Open Apex; Perforation Repair; Periapical Pathology; Resorption

Introduction

Biodentine is a “bioactive endodontic cement”, which implies the release of calcium ions, electroconductivity, production of calcium hydroxide, formation of interfacial layer between the cement and the cementum / dentinal wall, and formation of apatite crystals over the surface of material in a synthetic tissue fluid environment such as phosphate buffer solution [1,2]. Most of the bioactive endodontic cements available in market are either calcium silicate or calcium...
aluminate-based [1]. Biodentine is a tri-calcium silicate containing cement with the unique characteristics of rapid setting, development of early high strength, and a higher reactivity than other calcium silicates [1]. Biodentine is presented as powder/liquid system comprising a powder of tri-calcium silicate, di-calcium silicate, calcium carbonate, CaO and zirconium oxide as radio pacifier. Liquid consists of calcium chloride and a hydro soluble polymer. Biodentine was developed as a multipurpose, dentin and root replacement material and has been shown to exhibit excellent biocompatibility properties [3,4].

This case series report contains some common clinical indications where Biodentine been used successfully and some off-label usage of this material, which has enabled successful clinical outcomes. Cases present in the report are from the year 2016 to the present date.

**Clinical Cases**

**Perforation Management**

Two patients with complaints of pain in relation to root canal treated teeth reported to department in years 2010 and 2011. On radiograph examination indicated there was a perforation and missed canal (Fig. 1). The missed canal was treated and obturated with gutta-percha and zinc oxide eugenol sealer. The perforation was sealed with glass ionomer cement; this material has been shown to demonstrate inferior outcomes compared to bioactive cements in perforation sealing.

![Figure 1: A, B, C: Mandibular central incisor perforation management with glass ionomer cement. Arrows point to area of perforation. D, E: Mandibular second molar perforation in the mesial root managed with glass ionomer cement. Arrows point to area of perforation.](image-url)
In 2016, a 45 yr-old female patient with pain in relation to an attempted root canal procedure on the right maxillary first molar presented for treatment. The periapical radiograph showed a perforation in close proximity to the mesio-buccal canal orifice (Fig. 2). Perforation management was done using an operating microscope; placing Biodentine in more precise manner.

![Figure 2: A: Pre-operative radiograph of right maxillary first molar arrows point to perforation close to mesio-buccal (MB) root. B: Under operating microscope magnification the perforation (arrow) is located. C: Root canal file placed in the perforation. D: Perforation sealed with Biodentine (arrow). E: Post-obturation periapical radiograph.](image)

In 2019, a female patient aged 40 years reported with complaints of pain in relation to root canal treated left mandibular first and second molar and periapical radiographic examination showed 3 major errors; a perforation, root canal instrument separation and gutta percha points beyond apex in both the molar teeth (Fig. 3A). Root canal retreatment and perforation management with Biodentine was completed using an operating microscope followed by a proper coronal restoration (Fig. 3A i-x1).

A 20 yr-old male patient reported for post-endodontic restoration for root canal treated left mandibular first molar teeth, for which there was significant loss of tooth structure. A fiber post placement was recommended in the distal canal of tooth (Fig. 3B). During post space preparation a strip perforation occurred, which was managed with Biodentine using an operating microscope followed by an endocrown as post-endodontic restoration (Fig. 3B ii-vii).
Figure 3: Ai: Pre-operative radiograph of inadequately root canal treated left mandibular first and second molar with instrument separation and gutta percha points beyond apex. Aii: Gutta percha point removed from the left mandibular first molar. Aiii: Perforation (arrow) detected near the distal canal of the left mandibular first molar under operating microscope. Misdirection during access preparation resulting in a perforation is a common risk associated with Pulp Canal Obliterated (PCO) traumatized maxillary incisor teeth. In 2017, a 35 yr-old male patient presented with complaints of pain and discoloured maxillary incisors. Radiographic examination indicated there was a misdirected access preparation in the maxillary left central incisor that resulted in a perforation (Fig. 4). On Cone Beam Computed Tomography (CBCT) scan examination the precise location of the perforation was assessed. Canal was traced by extending the access preparation using ultrasonic diamond abrasive tips and the canal was obturated with gutta-percha and sealer. The perforation was closed with Biodentine and the tooth was restored with a full coverage ceramic crown. Two-year post-treatment CBCT and radiograph images show no evidence of alveolar bone loss and excellent periapical healing (Fig. 4G,H).

E: Post-obturation radiograph with Biodentine sealing of the perforation. F: Two year post-treatment radiograph demonstrating intact alveolar crestal bone height (arrow) and excellent periapical healing (arrow). G: Two year post-treatment CBCT image shows intact alveolar crestal bone height (arrow) in the left maxillary central incisor. H: Full coverage ceramic crowns placed to correct the labial proclination and spacing from left maxillary lateral incisor to right maxillary lateral incisor.

External Resorption Management

The use of Biodentine has provided excellent post-treatment results in management of external root resorption due to various etiologies. In 2017, a 46 yr-old female patient presented with complaints of discoloration and pain in a previously traumatized maxillary left central incisor. On radiographic examination there was external cervical resorption on the root, which was confirmed with CBCT (Fig. 5 A). The root canal was obturated with Biodentine as sealer and thermoplasticized gutta-percha. The resorptive defect was restored following a full thickness muco-periosteal flap reflection with resin-modified glass ionomer cement and using Biodentine as a base.

In 2018, a 45 yr-old male patient presented with complaints of pain in traumatized maxillary right central incisor; a periapical radiograph showed a cervical resorptive defect (Fig. 5 B). A CBCT scan detected external resorption in the maxillary right central incisor. The apical one-third of root canal below the resorptive defect was obturated with thermoplasticized gutta-percha, using Biodentine as root canal sealer. The resorptive defect was restored with Biodentine as a base and resin modified glass ionomer cement following palatal full thickness muco-periosteal flap reflection (Fig. 5B). The access preparation was restored along with resorptive defect with Biodentine base and resin modified glass ionomer cement.

In 2017, a 52 yr-old female patient reported to the department for root canal treatment in left maxillary second molar tooth. Upon close examination of the periapical radiograph, the disto-buccal root showed evidence of resorption, which was confirmed with a CBCT scan (Fig. 5C). The disto-buccal root was obturated with Biodentine cement, while the rest of the root canals...
were obturated with a single-cone greater taper gutta-percha cones and zinc oxide eugenol sealer. A two-year recall radiograph showed the root canal treated tooth with no progression of resorption or development of periapical pathosis (Fig. 5C).

Biv: Palatal full thickness muco-periosteal flap reflected to access the resorptive defect (arrow). Bv: Resorptive defect sealed with Biodentine base (arrow). Bvi: Biodentine also placed through the access preparation to allow for better sealing of the cervical resorptive defect. Bvii: Post-treatment radiograph displaying canal obturation and resorptive defect sealing.

**Ci:** Left maxillary second molar radiograph showing evidence of disto-buccal root resorption (arrow). Cii: Pre-operative CBCT image show external resorption (arrow) in the disto-buccal

**Replacement Resorption Management**

In June 2019, a 17 yr-old male patient with pain in a traumatized maxillary right central incisor reported to department. The patient gave a history of replacement of both the maxillary central incisor following avulsion. A periapical radiograph showed complete resorption of maxillary left central incisor root and right central incisor had extensive external replacement resorption approximating the pulp canal space (Fig. 6). Root canal was completed with Biodentine as the obturation material. An 8-month review radiograph and CBCT scan indicated there was no progression of the resorptive defect (Fig. 6).

**Figure 6:**

B: Pre-treatment photograph displaying ankylosed and infra-occlusion position of left maxillary central incisor and labial positioning of right maxillary central incisor.

C: Post root canal treated right maxillary central incisor (arrow) canal filled with Biodentine.

D: Eight months post-treatment CBCT image displaying non-progression of the external resorptive defect (arrow).

E: Eight months post-treatment radiograph showing the non-progression of the replacement resorption.
**Root Fracture Management**

A 25 yr-old male patient reported to department with complaints of pain in fractured right maxillary central incisor in the year 2017 (Fig. 7). Radiographic examination showed a horizontal root fracture in maxillary left lateral incisor below the alveolar crest bone. The fractured root segment below the fracture line and alveolar crestal bone was not able to be accessed. The coronal fracture segment had no mobility the pulp chamber and the root canal portion in this segment was cleaned, shaped and obturated with Biodentine cement (Fig. 7).

Sixteen months later the patient reported for replacement of the avulsed left maxillary central incisor. A periapical radiograph of maxillary left lateral incisor at this time showed an intact apical root segment with continuous lamina dura and PDL width in normal dimensions (Fig. 7).

**Figure 7:** A: Pre-operative radiograph of left maxillary lateral incisor with horizontal root fracture (arrow) below the alveolar bone crest level. B: Coronal segment of the root coronal of fracture line is cleaned and shaped. C: Coronal segment of root portion of left maxillary lateral incisor (arrow) is filled with Bio-dentine. D: 16-months post-treatment photograph of the left maxillary lateral incisor (arrow). E: 16-months post-treatment radiograph showing intact PDL width and lamina dura in left maxillary lateral incisor (arrow).
Immature Traumatized Necrotic Pulp (Open Apex) Maxillary Incisor Management

The management of this procedure and its outcome evaluation are registered with clinical trial registry of India (CTRI/2020/02/023309). The use of Biodentine as obturating material or as apical root canal plug in immature maxillary incisors with necrotic pulps was initiated in 2016. For the first two years of this trial, the entire canal obturation was done with Bio-dentine; beginning in 2018 its use was changed to an apical plug. Armamentarium used for management of apically wide open canals is shown in Fig. 8A, along with its application. In the initial year only the post-treatment outcome was planned for evaluation with CBCT scans (Fig. 8). However, in 2017 a decision was made to assess the pre- and post-operative status of these teeth with CBCT scans (Fig. 8). Thus far, 58 teeth from 54 patients with preoperative CBCT scans have been managed. Root canals of these teeth are minimally instrumented and working length is determined using a phosphate plate sensor; irrigation is done with normal saline solution activated with ultrasonic activation; Triple-Antibiotic Paste (TAP) was used as intracanal medicament for 15 days. Obturation of root canal was completed with a Biodentine apical plug and the canal was back-filled with thermoplasticized gutta-percha. Thirty-five (35) patients have returned for evaluation with 12 ± 2 months post-treatment CBCT scans (Fig. 8). Excellent periapical healing was noted in all the post-treatment CBCT scans. The main drawback of this procedure was discoloration of the tooth caused by TAP, but this was reversed with three-sittings of walking bleaching using sodium perborate and 37% hydrogen peroxide followed by composite restoration or full coverage ceramic crowns (Fig. 9).

**Healing of Periapical Pathosis When Biodentine is used as a Root Canal Sealer**

A 27 yr-old female patient with complaints of pain in her traumatized left maxillary central incisor reported to the department in 2017. Radiographic data, CBCT scan and clinical examination indicated that the tooth had a necrotic pulp with periapical lesion (Fig. 10). The tooth was managed by non-surgical root canal treatment with calcium hydroxide intra-canal medicament for 1-week, ultrasonic irrigation activation followed by thermoplastic obturation with Biodentine as root canal sealer. Sixteen months following root canal treatment the patient returned for assessment and a CBCT scan showed excellent periapical healing and resolution of the periradicular pathosis (Fig. 10).

A 23 yr-old male patient with complaint of pain in a mandibular left second molar tooth reported to the department in 2018. On clinical examination a deep caries with pulpal involvement and a non-draining extra-oral sinus tract was present near the angle of mandible. Radiographic and CBCT examination confirmed the pulpal involvement and a periapical radiolucency evidencing erosion of the lingual cortical plate (Fig. 10). Non-surgical root canal treatment was the preferred treatment using Bio-dentine. At twelve months a CBCT scan showed complete resolution of the periapical lesion (Fig. 10).

**Figure 10:** A: Pre-operative CBCT image of left maxillary central incisor with periapical pathosis (arrow). B: 16-months post-treatment CBCT scan exhibiting periapical resolution.
Surgical Management of Peripical Lesions of Pulpal-Origin with a Biodentine Apical Plug

Periapical surgery with curettage with or without root-end resection was chosen for teeth exhibiting perapical radiolucencies with cortical plate involvement, as evidenced in CBCT scans. The teeth were obturated prior to surgery with a Biodentine apical plug and thermoplasticized gutta-percha backfill of the canal. The apical plug served two purposes:

1. Placement of this bioactive material in contact with periradicular tissues
2. If a root-end resection was done more surface area of Biodentine would be in contact with the periradicular tissues, thereby negating the need for a root-end filling

A 13 yr-old male patient was referred to the department in 2018 with complaints of pain and swelling in the mandibular anterior region (Fig. 11). On clinical examination both mandibular central incisors had necrotic pulps and right mandibular central incisor was rotated along with a lingually placed right mandibular lateral incisor (Fig. 11). The patient reported a history of trauma to his mandibular incisors two years prior. CBCT scan examination showed a large periapical radiolucency involving the two central incisors, along with labial cortical plate erosion (Fig. 11). To alleviate the abscess that was present, an incision and drainage was performed. Root canal treatment of the two mandibular central incisors was completed as per earlier mentioned protocol. Surgical treatment option was chosen using Bio-dentine; periapical curettage was performed without root-end resection (Fig. 11), and Platelet-Rich Fibrin (PRF) was placed as graft material in bony defect. Histopathological examination of the curetted tissue indicated a periapical granuloma. A 12 months post-treatment CBCT scan showed excellent periapical healing, with resolution of the periapical radiolucency and bone regeneration (Fig. 11).

A 21 yr-old female patient reported to department in 2019 with complaints of pain in root canal treated left maxillary central and lateral incisors that were restored with ceramic crowns (Fig. 11). Radiographic examination indicated that the previous root canal treatment was inadequate and a large periapical radiolucency involving the roots of the left maxillary central and lateral incisors was present (Fig. 11). CBCT scan examination showed the periapical radiolucency had eroded the labial cortical plate (Fig. 11). The ceramic crowns were removed followed by completion of root canal treatment with Biodentine apical plug obturation (Fig. 11). Root-end resection of both the right maxillary central and lateral incisors was performed along with a PRF graft material in the bony defect (Fig. 11). Histopathological examination showed
scattered areas of epithelial lining in the curetted tissue and a diagnosis of periapical granuloma with isolated cystic elements was given. Post-endodontic restorations with new lithium-disilicate full coverage crowns were placed (Fig 11). 12-months post-treatment CBCT scan showed excellent periapical healing and bone regeneration (Fig 11).

Intentional Pulpotomy in Amelogenesis Imperfecta Management

A 17 yr-old female patient reported to the department for management on unaesthetic appearance of her teeth in the year 2019 (Fig. 12). Upon clinical examination she was diagnosed as having amelogenesis imperfecta. An orthopantogram showed no caries, pulpal or periapical pathosis (Fig. 12). She was advised to have metal-free lithium di silicate ceramic crowns for her maxillary and mandibular teeth. Crowns were delivered from left second premolar to right second premolar. Previous experience with Biodentine pulpotomies for sensitive, attrited molar teeth prompted us to have the teeth to be restored with crowns to have Biodentine pulpotomies prior to tooth preparation (Fig. 12) [5]. The rationale for choosing pulpotomy was to prevent pulpal damage during extensive tooth preparation required for metal-free ceramic crowns.

In addition to the cases presented here, Biodentine has been used in other clinical scenarios, such as the management of dens invaginatus [6].

DOI: http://dx.doi.org/10.46889/JDHOR.2020.1206
Conclusion

Better understanding of progression of pulpal pathology and periapical healing has allowed for the use of bioactive materials, such as Bio-dentine, for more conservative treatment options, thereby avoiding extensive and invasive procedures in preserving the tooth and dentition.
